Toward photodetector arrays based on indium gallium nitride micro-LEDs

Researchers implement a 2-transmitter, 2-receiver visible light communication setup with data rates up to 175MHz.

Fudan University in China and University of Toronto in Canada have been exploring the use of indium gallium nitride (InGaN) micro-light-emitting diode (µLED) arrays in photodiode (PD) mode for multiple input, multiple output (MIMO) visible light communications (VLC) [Xiaoyan Liu et al, ACS Photonics, (2019) vol6, no12, p3186]. The team suggests that the technology could lead to integration of display, fast data transmission and photodetectors, powered photovoltaically either through the signal itself or through solar illumination.

The researchers comment: "Such a multifunctional µLED information display is very useful for applications where high-speed wireless network

Figure 1. (a) Schematic diagram of µLED, (b) setup for MIMO VLC, and (c) photograph of experiment.
and considerable electrical power are required, for instance information display chips for wearable virtual reality/augmented reality (VR/AR) devices, and outdoor large-screen display.”

VLC is seen as a wireless communication technology that could be deployed in environments where electromagnetic interference from radio frequencies could be problematic such as aircraft or hospitals.

The small size of µLEDs is expected to result in higher bandwidths due to smaller parasitic resistances and capacitances. Although single µLED photodetectors have been studied, the researchers report that parallel array structures of such devices have not been presented up to now.

The 2x2 MIMO system consisted of transmissions from 405nm violet laser diodes (LDs) transmitted over a free-space distance of 1m onto 450nm blue µLED structures used as photodetectors (Figure 1). The laser diodes were used due to reduced crosstalk between the two signal sources with reduced divergence angle of the beams. The laser light was collimated using lens systems.

The researchers fabricated their devices using commercial metal-organic chemical vapor deposition (MOCVD) material grown on patterned sapphire substrates. The light-sensitive region was indium gallium nitride (InGaN) multiple quantum wells (MQWs) with GaN barriers. An aluminium gallium nitride (AlGaN) electron-blocking layer was included in the structure. The silicon dioxide (SiO2) insulation was applied using plasma-enhanced chemical vapor deposition (PECVD). Nickel/gold (Ni/Au) was used for current spreading. The n- and p-contact pads consisted of titanium/gold (Ti/Au).

The photodetector diameters varied between 40µm and 100µm. At zero bias, the photo/dark current ratio, or ‘photosensitivity’, was of order 10^9. This high value resulted from the very low dark current at zero bias of 10^-14A. The laser diode power density reached as high as 11.0W/cm².

With the devices biased at -5V, the photo/dark current ratio was 10^7 for the smaller devices, and 10^8 for the larger. The researchers say that these values match the best reported results and are “higher than previously reported values of the GaN photodetectors with photoconductive, p–i–n, or heterojunction structures”. The team expects the high values to benefit the signal/noise ratio and minimum detection limits of the devices.

When the illumination was at 11.0W/cm², the short-circuit current was 27.4µA for the 40µm-diameter µLED. This increased to 188µA for 100µm diameters. The open-circuit voltages were all 2.6V. This photovoltaic effect could be used to power other parts of a circuit. The researchers report that they have used such harvested energy to power a 660nm laser diode.

The team sees potential for such setups to be used in powering systems in hazardous and harsh environments.

The responsivity of the self-powered µLEDs with 11.0W/cm² laser power density was 0.24A/W for 40µm diameters, and 0.21A/W for 100µm. A 60µm-diameter
µLED achieved 0.29A/W response. The researchers estimate the quantum efficiency to be 74%, 88% and 62% for 40µm-, 60µm- and 100µm-diameter µLEDs, respectively.

Biasing the devices at −5V gives corresponding responses of 0.27, 0.31 and 0.24A/W — and quantum efficiencies of, in the same order, 82%, 96% and 73%. The researchers attribute the increased performance to the enhanced separation and collection of electrons and holes under reverse bias.

The team comments: “The values of responsivities are higher than that of a commercial Si-PIN photodetector at the wavelength of 405nm and are slightly better than the GaN-based photodetectors in previous reports without internal photocurrent gain.”

The specific detectivity that measures the effects of bandwidth and noise on the µLED-PD was around $10^{13}$Jones (cm-Hz$^{1/2}$/W) at zero bias — $7.5 \times 10^{12}$ones for 40µm diameters and $1.5 \times 10^{13}$ones for 60µm. The values decreased somewhat for −5V bias due to increased dark current — $1.11 \times 10^{11}$ones for 40µm and $2.3 \times 10^{12}$ones for 60µm diameters.

For high-speed communications, fast response to changes in illumination are needed. Smaller devices are likely to have faster rise and fall times. At zero bias, the rise and fall times in response to 11.7W/cm$^2$ laser diode illumination were 22.0ns and 23.7ns, respectively, for the 40µm-diameter µLED. These times reduced with −5V reverse bias to 13.2ns and 13.7ns, respectively.

The researchers explain: “In comparison with 0V bias, the photoresponse time turns out to be shorter at a −5V bias, which is attributed to the increase of drift speed of carriers under reverse bias.

In fact, the 60µm-diameter µLED had improved rise/fall times: 17.2n/20.2ns at zero bias, and 12.2ns/12.7ns at −5V.

The −3db electrical-to-optical modulation bandwidths at −5V reverse bias were 56.8, 56.2 and 53.5MHz, respectively, for the 40µm, 60µm and 100µm devices. These values reduced at zero bias with corresponding values of 40.3, 41.2 and 38.6MHz.

In on-off keying (OOK) modulation transmissions, the researchers achieved 185 megabits per second (Mbps) with the 100µm device reverse biased at −5V (Figure 2). The bit error rate (BER) was $3.5 \times 10^{-3}$, lower than the 3.8$ \times 10^{-3}$ upper limit for forward error correction (FEC) to be possible.

The 60µm device achieved 120Mbps with zero bias and 3.6$ \times 10^{-3}$ BER. Under −5V reverse bias, the same devices achieved 175Mbps and 3.7$ \times 10^{-3}$ BER. The researchers comment: “In the proposed 2x2 MIMO VLC, ideal real-time data rates of 350Mbps (under a −5V bias) and 240Mbps (under zero-bias) can be accomplished using 60µm µLED-based photodetectors as optical receivers.”

Applying scaling arguments, the team suggests that 18Gbps could be achieved with 10x10 arrays, and several terabits per second with 128x128 setups. However, “it is worth noting that there are significant challenges to achieve such extension to multi-Gbps transmission in practical applications because of the inevitable crosstalk and collimation difficulty for more and more arrays,” the team warns.
